The Marne–Saunders Prescribed Water Resources Area (PWRA) is located on the eastern side of the Mount Lofty Ranges about 60 km northeast of Adelaide. It is a regional scale resource for which surface water and groundwater is prescribed under South Australia’s Natural Resources Management Act 2004. A Water Allocation Plan provides for sustainable management of the water resources.

The Marne–Saunders PWRA is a tributary catchment for the River Murray which can be divided into two distinct groundwater regions: the Hills Zone and the Plains Zone. Overall, extractions for the whole PWRA totalled 1845 ML for 2009 – 10.

The Hills Zone comprises fractured rock aquifers of the Mount Lofty Ranges. Metered extractions from these aquifers have declined over recent years in response to better rainfall. The volume for 2009–10 was 279 ML which represents a decrease of 15% from the previous year. Lucerne was the largest user accounting for 60% of the extraction and vines were the second largest user with 34% of the extraction. Extraction volumes are considered too low and dispersed to affect regional trends. Groundwater level monitoring shows a strong relationship with rainfall patterns.

In the Plains Zone irrigation supplies are obtained from the Murray Group Limestone aquifer, predominantly along the Marne River valley. Metered extractions for 2009–10 totalled 1566 ML, a decrease of 18% from the previous year. Again, lucerne was the largest groundwater user accounting for 70%.

Below average rainfall in the Hills Zone has resulted in very little streamflow and consequently little recharge to the limestone aquifer where it is unconfined downstream of Cambrai. Groundwater levels on the Plains Zone along the river valley are consequently at their lowest ever recorded levels since monitoring began in 1980. Groundwater salinities in this aquifer are showing a gradual rise because of the lack of recharge from streamflow infiltration.

There are no significant adverse trends in the fractured rock aquifer or the limestone aquifer where it is confined upstream of Cambrai.
ASSESSMENT OF STATUS

The Marne-Saunders PWRA has been assigned a status of yellow “Adverse trends indicating low risk to the resource in the medium term” for the 2009–10 water use year. This status is supported by:

- a gradual decline in groundwater levels on the Plains Zone since 2006 due to lack of recharge from streamflow. These declines are not expected to affect access to the resource by groundwater users over the next 10 – 20 years.
- a gradual increase in some salinity levels since 2006 on the Plains Zone due to lack of recharge from streamflow. These increases are not expected to affect the current beneficial use of the resource by groundwater users over the next 10 – 20 years.

The observed trends highlight the importance of recharge from streamflow for the sustainable development of the groundwater resource on the Plains Zone. A prolonged period of limited or no streamflow could exacerbate the adverse trends.

There are no significant adverse trends in the fractured rock aquifer or the limestone aquifer where it is confined upstream of Cambrai.

STATUS (2009 – 10)

- **Green** No adverse trends, indicating a stable or improving situation
  - Trends are either stable (no significant change), or improving (i.e. decreasing salinity or rising water levels).
- **Yellow** Adverse trends indicating low risk to the resource in the medium term
  - Observed adverse trends are gradual and if continued, will not lead to a change in the current beneficial uses of the groundwater resource for at least 15 years. Beneficial uses may be drinking water, irrigation or stock watering.
- **Orange** Adverse trends indicating high risk to the resource eventuating in the short to medium term
  - Observed adverse trends are significant and if continued, will lead to a change in the current beneficial uses of the groundwater resource in about 10 years.
- **Red** Degradation of the resource compromising present use within the short term
  - Trends indicate degradation of the resource is occurring, or will occur within 5 years. Degradation will result in a change in the beneficial use (i.e. no longer suitable for drinking or irrigation purposes) and may take the form of increasing groundwater salinities, or a fall in the groundwater levels such that extractions from the aquifer may not be possible.
The Marne-Saunders PWRA is located about 60 km northeast of Adelaide on the eastern side of the Mount Lofty Ranges (Fig. 1) and comprises a tributary catchment for the River Murray which generates ephemeral flows in wet years. It is a regional scale resource for which surface water and groundwater are prescribed under South Australia’s *Natural Resources Management Act 2004*. A Water Allocation Plan, which was adopted in January 2010, provides for sustainable management of the resource.
HYDROGEOLOGY

The Marne–Saunders PWRA can be divided into two distinct groundwater regions; the Hills Zone and the Plains Zone. The Hills Zone comprises the consolidated basement rocks of the Mount Lofty Ranges, which form fractured rock aquifers (Table 1 and Fig. 2). Well yields are generally low (generally below 2 L/s). The Plains Zone is underlain by unconsolidated sediments of the Murray Basin (Table 1 and Fig. 2).

The main aquifer is the Murray Group Limestone, which is mostly developed along the Marne River for irrigation and is recharged mainly by infiltration of streamflow from the rivers as they flow out of the hills onto the plains. Groundwater level trends have shown a close correlation with streamflow and hence, rainfall in the Mount Lofty Ranges. Very little information is available about the underlying Renmark Group confined aquifer which comprises interbedded sands and lignitic (brown) clays, but yields are thought to be low.

GROUNDWATER FLOW AND SALINITY

Hills Zone
A groundwater level contour map for the fractured rock aquifer was not generated because of the highly variable ground elevations and limited coverage of observation wells. However, groundwater flow within the fractured rock aquifer in the Hills Zone generally follows topographic contours and flows from high points in the catchments to the low points where groundwater usually discharges to streams (Fig. 3). Groundwater also moves eastward from the Ranges, with discharge to the sedimentary aquifers on the Plains Zone. Salinities within the fractured rock aquifer are highly variable, with values ranging from 500 to 7000 mg/L.

Plains Zone
Figure 4 presents the water level elevation contours and salinity distribution for the Murray Group Limestone aquifer in the Plains Zone. Groundwater flow is generally in an easterly direction from the Hills Zone toward the River Murray in the Marne catchment, but tends toward a south–easterly direction in the Saunders catchment.

The salinity distribution reflects the source of recharge to the limestone aquifer. The low salinity zone adjacent to the faulted contact with the Hills Zone occurs where the limestone aquifer is confined by 60 m of clay (Pooraka Formation) as shown in Figure 2, and is unlikely to have received recharge by percolation from streamflow. Recharge by sub-flow from the fractured rock aquifers in the Hills Zone is more probable.

Further downstream to the east, a second low salinity zone near Kongolia indicates where the clay layer has thinned out and allowed direct infiltration of streamflow which has recharged the limestone aquifer.

GROUNDWATER DEPENDENT ECOSYSTEMS

Whilst groundwater dependent ecosystems (GDEs) have not been used in the assessment of the status of the groundwater resource, it is important to note the presence and ecological characteristics of the GDEs in the Marne–Saunders PWRA. Groundwater dependent ecosystems can be defined as ecosystems where groundwater provides all or part of the water quantity, chemistry or temperature requirements, either permanently, seasonally or intermittently. It is generally considered that shallow watertables less than 10 m below the surface are more likely to support GDEs than deeper watertables. The exception to this is stygofauna (animals that inhabit water filled spaces and pools below the ground), which can be found at greater depths.

Permanent pools exist throughout the upper watercourses that flow through the Marne–Saunders PWRA, most of which are expected to be maintained through groundwater baseflow contributions from the fractured rock aquifer. These permanent aquatic habitats are important refugia for aquatic biota and are known to support diverse populations of aquatic plants, aquatic macroinvertebrates and fish.

On the Plains Zone, baseflow from the regional limestone aquifer provides a key water source in some localised areas where the river channels have been incised down to the level of the watertable close to the River Murray. This is particularly important in the Marne River downstream of Black Hill and in the Saunders Creek near Lenger Reserve. These pools support one of only four known remaining populations of River Blackfish in the South Australian Murray–Darling Basin. River Blackfish are protected under South Australia’s Fisheries Management Act 2007.

Plants with a dependence on groundwater also exist along the watercourses within the PWRA and largely consist of River Red Gum (Eucalyptus camaldulensis). Other possible GDEs in the Marne–Saunders PWRA include stygofauna.
The climate of the Marne–Saunders PWRA is characterised by hot, dry summers and cool to cold, wet winters. Rainfall is highest in the Hills Zone at the western edge of the PWRA. Rainfall declines rapidly towards the east in the rain shadow of the Mount Lofty Ranges, at the confluence of the Marne River and the River Murray (Fig. 5).

Figure 5. Rainfall distribution across the Marne-Saunders PWRA

The cumulative deviation from the mean monthly rainfall for Mount Pleasant (station 23737) and Kongolia (station 24513) are graphed in blue in Figures 6 and 7 to identify periods where monthly rainfall trends are above or below average. An upward slope indicates a period where the rainfall is greater than the average, while a downward slope indicates a period where the rainfall is below the average. The location of both rainfall stations are shown in Figure 5.

The results show alternating above and below average trends lasting between 15 and 25 years. Since about 1975, significant periods of below average rainfall have been experienced, with the exception of very wet years in 1981, 1992–93 and 1996. This extended dry period would have a very strong impact on streamflow, and hence recharge to the aquifer on the Plains Zone.
Figure 6. Annual rainfall and cumulative deviation from mean monthly rainfall for the Mount Pleasant station adjacent the Marne–Saunders PWRA

The rainfall data for Kongolia located on the Plains Zone shows a much lower and more consistent rainfall over the past 40 years than recorded at Mount Pleasant (Fig. 6). This rainfall has only a slight impact on groundwater levels beneath the Plains Zone, away from the influence of infiltration from the Marne River.
Meters have been installed on all irrigation wells in the Marne–Saunders PWRA since 2002 in response to the prescription of the water resources. The metered groundwater extraction for the PWRA totalled 1845 ML for 2009–10 and is divided into the two aquifer categories (Fig. 8). Extractions from the fractured rock aquifer in the Hills Zone have declined over recent years since the 2006 drought in response to better rainfall, while extractions from the limestone aquifer in the Plains Zone have returned to long term average levels after a sharp rise last year. Actual values for 2009–10 were 279 ML for the fractured rock aquifer (a decrease of 15% from the previous year) and 1566 ML for the sedimentary (limestone) aquifer (a decrease of 18% from the previous year).

Extraction volumes from both aquifers are well below the extraction limits as shown in Figure 8.

![Figure 8. Historical licensed groundwater use in the Marne–Saunders PWRA](image)
Figures 9 and 10 show the volume applied to the various irrigated crops in 2009–10 for the two aquifers. Lucerne accounted for 60% and 70% respectively of the total extraction volume in both Hills and Plains Zones. Vines are the second largest user in the Hills Zone, while turf is the second largest in the Plains Zone.

GROUNDWATER OBSERVATION NETWORKS

WATER LEVEL NETWORK

The groundwater level observation network for the Marne-Saunders PWRA is shown below in Figure 11. Although monitoring commenced in 1980 with 11 wells, there are currently 54 wells being monitored as described in Table 2. The limited extraction in other parts of the PWRA has meant that most of the monitoring effort is concentrated on the limestone aquifer on the Plains Zone with a two–monthly frequency.

SALINITY NETWORK

The groundwater salinity observation network for the Marne–Saunders PWRA is shown below in Figure 12. The limited extraction in other parts of the PWRA has meant that most of the monitoring effort is concentrated on the limestone aquifer on the Plains Zone. Monitoring commenced in 1990, with eight wells monitored on a six monthly basis (Table 3).

STREAMFLOW TRENDS

The majority of streamflow is generated in the Hills Zone where rainfall is highest, with very little contribution from runoff in the Plains Zone. Flows vary considerably from year to year, as a result of the high variability in annual rainfall. Over the period 1973 to 2008, measured annual flows at the Marne Gorge flow gauging station ranged from over 33,500 ML in 1974 down to 80 ML in 1982 for years with flow records which are shown in red in Figure 13. The pink values are modelled streamflow results obtained from a catchment surface water model. During these years there was no stream gauging information available.

Figure 13 shows that very little stream flow has occurred between 2005 and 2009. A large proportion of the streamflow flowing out onto the Plains Zone infiltrates through the streambed and recharges the underlying limestone aquifer and therefore, the resultant lack of recharge will have significant impacts on groundwater levels and salinity.

![Figure 13. Annual streamflow at the Marne Gorge flow gauging station in the Marne-Saunders PWRA](image-url)
GROUNDWATER LEVEL TRENDS

QUATERNARY AQUIFER

In 2001, several shallow observation wells were installed in the river alluvium downstream of Black Hill to monitor groundwater levels and salinity and their potential impacts on vegetation health and the sustainability of permanent pools (waterholes) that occur in the lower Marne valley.

There are two trends being observed in Figure 14. RIL014 is located upstream of a shallow basement outcrop exposed in the river valley. This outcrop concentrates regional groundwater discharge into the valley and acts as an underground ‘dam’ which maintains groundwater levels at a reasonably constant level. RIL013 is located downstream of this flow barrier and is showing a decreasing trend which reflects the low recent streamflow and possibly regional groundwater level declines due to reduced recharge.

![Figure 14. Groundwater level trends of the Quaternary alluvium aquifer in the Marne-Saunders PWRA](image)

MURRAY GROUP LIMESTONE AQUIFER

The Murray Group Limestone aquifer can be divided into two areas, a confined area between the Hills Zone and Cambrai and an unconfined area east of Cambrai where the confining Pooraka Formation thins (Fig. 1 and 2). The water level trends are very different in these areas. Drawdowns in the confined portion of the aquifer occur more quickly and are greater than drawdowns in the unconfined portion because they are an instant pressure response to pumping and lateral inflow from the Hills Zone. In an unconfined aquifer, drawdowns or rises due to recharge only occur when water physically drains into or out of the sediments, which is a much slower process.

Confined

Water level hydrographs in the confined limestone aquifer are shown below in Figure 15. ANG 25 is located near intensive irrigation and shows consistent seasonal drawdowns during the irrigation season of about 18 m. There is a slight downward trend in the recovered water level.

The other wells, ANG 54 and ANG 56, are located 800 m and 2 km south of ANG 25 respectively and show decreasing amplitude of seasonal drawdown with increasing distance from the irrigation extractions.
Figure 15. Groundwater level trends of the confined limestone aquifer in the Marne-Saunders PWRA

Unconfined

In the unconfined aquifer a strong relationship between groundwater levels and streamflow is evident (Fig. 16). The timing and quantity of streamflow is controlled by the rainfall in the upper Marne catchment in the Hills Zone and consequently, the groundwater levels in the Plains Zone close to the Marne River are also controlled by rainfall in the Hills Zone.

The amount of recharge from streamflow decreases with distance downstream and also with distance laterally away from the Marne River. This is illustrated by Figure 16, which shows the water level response for ANG 10 (3 km downstream from where recharge commences) is greater than ANG 14 (7.5 km downstream) and RIL 1 (15 km downstream). Below average rainfall in the Hills Zone area has resulted in very little streamflow and consequently little recharge to the aquifer. Groundwater levels on the Plains Zone along the river valley are consequently at their lowest ever recorded levels.

ANG 8 is located 6 km south of the Marne River and shows no response to streamflow, but reflects changes in diffuse recharge from rainfall. The gradual decline in the water level is due to recent below average rainfall.
Regional trends in the fractured rock aquifer in the Hills Zone generally reflect rainfall trends, with Figure 17 showing groundwater level rises in wet years such as 1992–93, 1996, and 2004–05. The blue line indicates the cumulative deviation from the mean rainfall for the winter months only. Below average winter rainfall since the 2006 drought has resulted in a declining trend. Extractions volumes are relatively small and too dispersed to affect regional trends.
GROUNDWATER SALINITY TRENDS

The groundwater salinity readings recorded from irrigation wells in the Plains Zone are quite variable as can be seen in Figures 18 and 19, with two trends emerging — rising and stable.

Wells showing rising trends

A number of wells show a rising trend but the pattern is not consistent. In Figure 19, ANG042 is showing a reasonably consistent rising trend of about 20 mg/L/y, but on closer examination, this trend only really becomes apparent after 2002. This is consistent with RIL007 which also shows a dramatic increase after 2002. Other wells have shown a stable trend for 10 – 20 years before showing a rising trend after 2006 (ANG043 in Fig. 18 and ANG017 in Fig. 19).

This process occurs as irrigation water is drawn up through the root system, with most of the dissolved salt accumulating in the root zone and not being taken up by the plant. This salt then percolates back down into the aquifer during subsequent irrigation applications or from rainfall recharge, resulting in a continuous cycle of increasing groundwater salinity.

Wells showing stable trends

ANG041 (Fig. 18) has shown a stable trend for about 15 years. The most interesting trend is from ANG018 which was rising at about 60 mg/L/y up until 2004. This well is situated in an irrigation area on the floodplain with a depth to the watertable of about 10 m. This rise could have been attributed to the recycling of irrigation water. However since then, the trend has stabilised with a marked seasonal variation which could reflect a change in irrigation practice.

Effects of Flood Events

Figures 18 and 19 both show evidence that most wells experienced a marked salinity decrease immediately after the 1996 flood event, with an equally sudden rise afterwards. It is understood that this occurred due to the rapid recharge of low salinity river water, causing a simultaneous rise in the watertable and a reduction in groundwater salinity. As the flood receded, any surface water on the floodplain drained slowly down to the watertable and flushed down salt which had been accumulating in the unsaturated zone.

Figure 13 shows that the last significant flows that would have recharged the aquifer occurred in 2004 and 2005. As no significant recharge has occurred since then, it is not surprising that salinities have increased as the more saline regional groundwater has moved in to replace the lower salinity recharged water as it is pumped out.
Figure 18. Groundwater salinity trends of the unconfined limestone aquifer in the Marne-Saunders PWRA

Figure 19. Groundwater salinity trends of the unconfined limestone aquifer in the Marne-Saunders PWRA
Within the confined portion of the limestone aquifer, groundwater flows from west to east. The groundwater salinity also increases from west to east. One of the risks of pumping from the confined aquifer is that excessive drawdowns may cause a reversal in groundwater flow which would result in an influx of more saline groundwater from the east. A line of observation wells is being monitored to detect if there is sustained flattening of the pressure gradient between pumping seasons or reversal of the pressure gradient, as this is a ‘trigger for action’ in the Water Allocation Plan.

Figure 20 shows the observed gradient during the non-pumping period in July 2009. The flow gradient from west to east was occurring at this point in time.

Figure 20. Confined aquifer flow gradient in the Marne-Saunders PWRA in July 2009
